Objectives: To collect demographic and clinical data on pediatric mandibular fractures and to assess temporomandibular joint (TMJ) dysfunction in patients with condylar and subcondylar (C/SC) fractures.

Setting: Tertiary care children’s hospital.

Patients: Of 164 patients with mandibular fractures, 83 (50.6%) had C/SC fractures, of which 45 (54.2%) completed the questionnaire.

Main Outcome Measures: Helkimo Anamnestic Dysfunction Index (Ai) quantification of TMJ dysfunction after C/SC fracture and treatment modality of C/SC fractures.

Results: Of the 164 patients, 122 (74.4%) were male (median age, 10.4 years; age range, 0.6-19.0 years). Of the 83 patients with C/SC fractures, 61 (73.5%) were male (median age, 9.1 years; age range, 1.1-18.7 years); 66 (79.5%) had unilateral fractures and 17 (20.5%) had bilateral fractures. The Ai distribution of the 45 patients who completed the questionnaire was as follows: 15 (33.3%) none, 6 (13.3%) mild, and 24 (53.3%) severe. Females have more severe dysfunction than do males (95% confidence interval, 1.6-140.0; \( P = .02 \)). No other significant predictors of treatment modality or TMJ dysfunction were identified. Patients with bilateral fracture are 8.1 times (95% confidence interval, 1.0-66.1 times; \( P = .05 \)) more likely to have closed reduction than are those with unilateral fracture.

Conclusions: This is one of the largest series of pediatric C/SC fractures reported in the recent literature. Findings are significant for increased severity of TMJ dysfunction in females and higher incidence of closed reduction in patients with bilateral C/SC fracture.

Facial fractures are an uncommon occurrence in children owing to differences in the ratio between cranial and facial volume in children vs adults. At birth, the ratio of cranial to facial volume is approximately 8:1. By the completion of growth, this ratio decreases to 2.5:1.\(^{1,2}\) As a result, young children are more likely to sustain a skull fracture from frontal impact, whereas adults are more likely to develop facial fractures.\(^{1,2}\) Despite the lower incidence of facial fractures in children, they do occur, and they account for 5% of all pediatric trauma.\(^{3}\)

Excluding nasal fractures, mandible fractures account for approximately one-third of all pediatric facial trauma.\(^{4}\) However, the management of pediatric mandibular fractures should be considered different from that of adults. In children, one must consider the potential disruption of growth centers, especially when managing condylar fractures. Also important to consider is that the deciduous teeth have short, bulbous crowns and are often poor abutments for wires or arch bars, making interdental immobilization significantly more challenging in children than in adults.\(^{3}\) The placement of wire through alveolar bone may damage developing permanent tooth follicles.\(^{5}\)

Although condylar and subcondylar (C/SC) fracture of the mandible is the most common fracture site in children, its treatment remains controversial, and it poses long-term functional sequelae. The optimal management of C/SC fractures in children has been the subject of debate throughout the literature for many years. It has been historically argued that condylar fractures in children may be the only...
skeletal fracture in which no attempt to regain anatomic reduction is necessary. Options for treatment include open reduction with intraosseous fixation and intermaxillary fixation, closed reduction with immobilization using intermaxillary fixation, and nonimmobilization with emphasis on early motion.

There have been few long-term surveys of functional outcome after condylar fractures in children, making a comparative assessment of optimal treatment all the more challenging. The goal of this study was to collect information on all pediatric mandible fractures occurring at The Children's Hospital, Aurora, Colorado, during the past 10 years. After identifying all patients who experienced C/SC fractures, we administered a follow-up telephone questionnaire to assess the degree of temporomandibular joint (TMJ) dysfunction and long-term functional outcome based on demographic and clinical data.

METHODS

After Colorado Multiple Institutional Review Board approval was obtained, we performed a 10-year (1999-2009) retrospective medical record review of all pediatric patients treated for a mandible fracture by members of the Department of Otolaryngology at The Children's Hospital. Demographic and clinical data collected about all the patients included age, gender, date of fracture, presence of unilateral vs bilateral C/SC fracture (termed laterality of fracture), presence of concomitant fracture with C/SC fracture, mechanism and velocity of injury, fracture location, type of management (medical or surgical), and date and type of surgical management, if applicable.

All the families in the C/SC fracture group were offered a questionnaire to assess functional disabilities related to the TMJ. The questionnaire was modeled after the 1993 questionnaire of Nørholt et al (Figure 1). Based on the response to the questionnaire, an Anamnestic Dysfunction Index (AI) score of 0 to 2 was assigned as described by Helkimo. An AI value of 0 (AI0) denotes no symptoms of dysfunction; AI1, mild symptoms described by Ferreira et al into 3 types: low, medium, and high velocity. Low-velocity injury includes a fall from ground level. Medium-velocity injury includes bicycle accident, sport, animal accident, assault, violence, and fall from a height above ground level. High-velocity injury includes motor vehicle crash (car, motorcycle, and all-terrain vehicle).

Fracture location was identified by reviewing hospital medical records, operative reports, and radiographic findings (a panoramic tomogram [Panorex; SS White Co, Holmdel, New Jersey] or computed tomography). The C/SC fractures were further categorized into distinct types: unilateral, bilateral, and concomitant (defined as unilateral or bilateral C/SC fracture in conjunction with an additional mandibular fracture site).

When age was used for comparison purposes, the classification based on eruption of primary and secondary dentition as described by Thoren et al was used. The classification breaks down the age range into 5 groups: group 1 (0-5 years), group 2 (6-9 years), group 3 (10-12 years), group 4 (13-15 years), and group 5 (16-18 years).

Summary statistics were used to describe patient demographic and clinical characteristics. Logistic regressions were used to examine the potential association between the 2 outcome measures of AI value and treatment modality compared with the following potential predictors: age, gender, treatment, velocity of injury, laterality of fracture, concomitant mandible fracture, and time from surgery to questionnaire completion. Univariate analysis was performed first, and variables with P ≤ .1 were entered into multivariate models to examine the association with the outcome while adjusting for the other covariates.

RESULTS

A total of 164 children were identified in the 10-year retrospective review. The mean patient age was 10.3 years (median age, 10.4 years; age range, 0.6-19.0 years). There were 122 males and 42 females (2.90:1 ratio). The distribution of patients by injury type was 42, 93, and 27 for high-, medium-, and low-velocity injuries, respectively. Two patients had an unknown mechanism of injury. Distribution of patient characteristics is seen in the Table. A total of 258 fractures were identified, and the distribution of the fractures is depicted in Figure 2.

Eighty-three of 164 patients (50.6%) were identified as having C/SC fractures. Their mean age was 8.9 years (median age, 9.1 years; age range, 1.1-18.7 years). There were 61 males and 22 females (2.77:1 ratio). The distribution of patients by injury type was 15, 50, 17, and 1 for high-, medium-, low-, and unknown velocity injuries, respectively. Sixty-six patients had unilateral C/SC fractures and 17 had bilateral fractures. Concomitant fractures occurred in 38 of the 83 patients with C/SC fractures. Twenty-six of the patients were managed medically, which consisted of a soft diet, analgesics, and warm
compresses. Fifty-six patients underwent closed reduction with maxillomandibular fixation using ivy loops or arch bars for an average of 25.7 days (range, 15-43 days). One patient underwent an open surgical reduction (Table).

The questionnaire was completed by 45 of the 83 patients (54.2%) with C/SC fractures. The demographic and clinical characteristics of this subgroup were similar to those of the total C/SC group (Table). The patient who underwent open reduction did not complete the questionnaire and, therefore, was not included in this portion of the data analysis. Therefore, this resulted in 2 treatment groups: medical treatment vs closed reduction. An Ai0 was found in 15 patients (33.3%), Ai1 in 6 (13.3%), and Ai2 in 24 (53.3%).

Univariate logistic regressions were used to examine the association of Ai value with the following independent variables: age, gender, laterality of fracture, presence of concomitant mandibular fracture, velocity of injury, treatment, and time from surgery to questionnaire completion. All the models met the proportional odds assumption, that is, the regression functions are parallel on the logistic scale for mild symptoms vs no symptoms and for severe symptoms vs mild symptoms of dysfunction. The variables of age ($P = .50$), presence of concomitant mandibular fracture ($P = .88$), velocity of injury ($P = .39$), treatment ($P = .36$), and time from surgery to questionnaire completion ($P = .99$) were not significant. The variables of gender ($P = .009$) and laterality of fracture ($P = .05$) had $P < .1$ and were, therefore, entered into the multivariate logistic regression model. This showed that gender is still significantly associated with the outcome adjusting for the laterality of fracture (odds ratio [OR], 15.0; 95% confidence interval [CI], 1.6-140.0; $P = .02$), whereas laterality of fracture is no longer associated with the outcome in the presence of the gender effect (OR, 0.5; 95% CI, 0.10-1.97; $P = .30$). Compared with males, females are 15 times more likely to show a worse Ai value for mild symptoms vs no symptoms and for severe symptoms vs mild symptoms of dysfunction (95% CI, 1.6-140.0; $P = .02$). In analyzing the Ai distribution by gender, findings included 15 males with Ai0, 5 males with Ai1, and 13 males with Ai2. This is compared with 0 females with Ai0, 1 female with Ai1, and 11 females with Ai2. Therefore, 92% of females reported severe TMJ dysfunction while 60% of males had either mild or no TMJ dysfunction following C/SC fracture.

The association between treatment modality and potential predictors, including age, gender, laterality of fracture, presence of concomitant mandibular fracture, and velocity of injury, was examined using logistic regression, where outcome was closed reduction vs medical management. The single patient with open surgical reduction was deleted from the analyses, which were, thus, performed using data from the 82 patients with C/SC frac-

![Figure 2. Distribution of the 258 mandibular fractures by region. Data are given as number (percentage). Adapted with permission from Encyclopedia Britannica, 2007 Encyclopedia Britannica Inc.](http://archotol.jamanetwork.com/pdfaccess.ashx?url=/data/journals/otol/20030/)
The results are significant for laterality of fracture (P = .04) and presence of concomitant fracture (P = .08) but not for age (P = .15), gender (P = .37), or velocity of injury (P = .28).

Laterality of fracture and presence of concomitant mandibular fracture were then entered into the multivariate regression model. This showed that laterality of fracture is still significantly associated with treatment modality (OR, 8.1; 95% CI, 1.0-66.1; P = .05), whereas the presence of concomitant mandibular fracture is no longer associated with the outcome (OR, 2.1; 95% CI, 0.8-5.8; P = .16). Patients with bilateral fracture are found to be 8.1 times (95% CI, 1.0-66.1; P = .05) more likely to have closed reduction than are patients with a unilateral fracture.

**Comment**

The management of pediatric C/SC fractures of the mandible has been a subject of debate for many decades. This has been due, in part, to the lack of implementation of a standardized, systematic method for assessing their functional outcomes. Multiple studies published in the past decade have sought to address these issues.

Norholt et al examined 55 pediatric patients who were medically treated for a fracture of the mandibular condyle and created a questionnaire to measure their functional outcome. He found that in younger children, a conservative treatment strategy is preferable, whereas older children had an often unsatisfactory outcome. A report of 26 condylar fractures by Thore`n et al concluded that no benefit was gained by maxillomandibular fixation and that a soft diet and immediate mobilization is the treatment of choice. Choi et al reviewed a series of 11 consecutive children and adolescents with condylar fractures who had been treated with conservative therapy. They concluded that nonsurgical management of condylar fractures in children results in a satisfactory long-term outcome despite abnormal radiographic findings. Deleyiannis et al reviewed 6 children 14 years or younger with a C/SC fracture who underwent open reduction with internal fixation. These patients were found to have outcomes similar to those of patients managed nonsurgically, and they concluded that until there is a distinct advantage to open surgery, these patients should be managed medically as a first-line treatment.

The present study provides the first large-scale review of pediatric mandible fractures in the past 10 years that collected demographic data on the entire population and provided data regarding TMJ dysfunction based on a follow-up questionnaire. The reported incidence of condylar fracture varies widely in the literature (19%-62%). Most studies have found an incidence of 19% to 50%. The preponderance of C/SC fractures in this series (50.6% of all patients and 41.4% of all fractures) is, therefore, at the high end or slightly higher than the incidence quoted in most other studies.

Regarding the outcome measure A, we noted a new finding of increased reported TMJ dysfunction in females compared with males. Multivariate analysis showed that this gender difference is not confounded by age, laterality, presence of concomitant fracture, velocity of injury, or treatment modality. These findings are in disagreement with studies in the literature that TMJ dysfunction correlates with increasing age. We did not see evidence of increased dysfunction with age in this patient population. The increased incidence of closed reduction treatment in the presence of bilateral fractures is an expected finding. The presence of a bilateral fracture would increase the likelihood of malocclusion or unstable fracture, requiring rigid fixation. In accordance with most previous studies, we did not demonstrate an improved outcome with surgical management of C/SC fracture compared with medical management.

The dreaded complication of a condylar fracture is the development of TMJ ankylosis with or without growth retardation, which is reported to occur in 1% to 7% of condylar fractures. Ankylosis of the TMJ is more likely to occur in children with bilateral condylar fractures, in children aged 2 to 5 years, if treatment is delayed, or if maxillomandibular fixation is prolonged. To our knowledge, none of the 45 questionnaire respondents had this complication. Yet, 53% of the respondents reported significant TMJ complaints (A2). This underscores that C/SC fractures in children have long-term consequences regardless of treatment strategies.

This study identified gender as a statistically significant factor in the outcome of TMJ function after C/SC fracture, a finding that has not been reported in previous literature, to our knowledge. A previous population-based epidemiologic study of adults by LeResche found that TMJ dysfunction is a disorder of adults and is less seen in children. He also found that TMJ pain and crepitus in the joint was universally found to appear about twice as frequently in women as in men. He did not find these gender differences to be present in children, however. When investigating possible etiologic factors, it was noted that life stress, depression, and the presence of multiple somatic symptoms are often found to be risk factors for TMJ pain, and these tend also to be reported more frequently in women. Female reproductive hormones have also been implicated in joint pain and pain syndromes, whereas testosterone in males may help attenuate pain symptoms. However, this would be less relevant in the pediatric population. Further investigation is warranted to determine whether other factors contribute to the increased level of dysfunction reported in female pediatric patients vs males in the present study.

The major limitations of this study rest in the intrinsic weakness of a retrospective review and in the reliance on an unvalidated instrument for the follow-up questionnaire. Yet, one has to recognize that a randomized clinical trial for the treatment of C/SC fractures is ethically and logistically difficult to accomplish. Furthermore, the internal and external validity of any TMJ dysfunction instrument is difficult to establish owing to the relative infrequency of this entity, as shown in the slow accrual of patients in this and other studies. Despite the retrospective nature of this study, closed reduction was found to be more likely to occur in children with bilateral C/SC fractures at The Children’s Hospital. Other factors, such as age, gender, presence of concomitant fracture, and velocity of injury, do not play a significant role.
in the surgical decision. In conclusion, this study represents one of the largest series of pediatric C/SC fractures to be reported in the recent literature. It combines a 10-year retrospective review of pediatric mandibular fractures with the collection of follow-up data regarding TMJ dysfunction. Increased reporting of TMJ dysfunction in females, although not thoroughly understood, stands out as the most significant finding of the study. Further study is warranted to determine whether there are other potential predictors of TMJ dysfunction that could then help guide management.
