Degenerative Changes in the Human Cricoarytenoid Joint

Friedrich P. Paulsen, MD; Bernhard N. Tillmann, MD

Objective: Changes in the human voice occur during the natural aging process. Occurrence of compromising alterations in the cricoarytenoid joint has been hypothesized as a possible reason for voice changes seen in advanced age and has been discussed controversially until today.

Methods: The present study analyzes degenerative changes in 42 cricoarytenoid joints from 21 donors (13 men and 8 women; age range, 42-98 years) by means of histological, immunohistochemical, and scanning electron microscopic methods.

Results: Many patients older than 40 years show distinctly altered joint surfaces at varying levels of intensity. The articular cartilage surface is fibrillated in some places. Chondrocytes near the joint surface appear as voluminous chondrocyte clusters. The superficial cartilage layer shows a positive reaction to type III and type I collagen antibodies.

Conclusions: Chondrocyte proliferation next to the joint surface, changed collagen synthesis, and fibrillation of the joint surface indicate degenerative alterations. Such changes are well known in cases of limb diarthroses. The changes may impair gross positional or postural movements of the arytenoid cartilages and reduce the degree and extent of vocal ligament closure. The structural changes may also lead to negative functional consequences during vocal production, such as impaired vocal quality and reduced vocal intensity due to air leakage through incompletely or loosely approximated vocal ligaments.

Degenerative joint diseases in limb joints are common in people older than 40 years. The incidence of osteoarthritis is approximately 100% in individuals between 70 and 80 years. The disease develops because of a lack of balance between quantity of joint load and load capacity of the supporting tissue involved in the composition of joint structures. Under these conditions, chondrocytes undergo metabolic changes in response to increased strain. Reduction of force uptake on the joint surface or increased external load are possible factors that may lead to an increased demand.

The human cricoarytenoid joint (CAJ) can be compared with the joints of limbs despite its structure and extracellular matrix composition. To date, little is known about the occurrence of degenerative changes in the human CAJ.

The present study analyzes the structure of CAJs of elderly individuals in terms of degenerative changes. Pathological findings are discussed in relation to resulting biomechanical function and then compared with degenerative changes of joints at the limbs.

RESULTS

The 21 investigated specimens showed degenerative changes in 1 or both CAJs (Table). Results are related only to the joints with an altered joint surface.

LIGHT MICROSCOPY

Degenerative articular cartilage of the cricoid and arytenoid facets showed numerous fibrillations, especially in the superficial cartilage layer (Figure 1). Adjacent to the fibrillations, there were several chondrocyte clusters consisting of 4 to 10 cells (Figure 1). They revealed marked Alcian blue staining (pH, 1.0) only around the clusters. Staining appeared to be reduced or absent in the surrounding territorial and interterritorial matrices.

Chondrocytes of deeper cartilage layers showed a normal aspect. Intensive staining of these chondrocytes and their territorial matrices with Alcian blue (pH, 1.0) was found throughout the deeper car-
MATERIALS AND METHODS

Forty-two CAJs (from 13 men and 18 women; age range, 42-98 years) obtained from 21 body donors from the Department of Anatomy, Christian-Albrechts-University of Kiel, Germany, showing an altered joint surface were chosen for the study after their joint capsules were opened and their joint surfaces investigated with a magnifying glass (Table). Limited information was available on the specimens, which were taken from individuals without recent trauma or diseases that might involve or affect laryngeal function.

The Table shows the investigative method used for each CAJ. Sixteen joints (from 10 men and 6 women; age range, 42-98 years) were fixed in 4% formalin, decalcified in 20% EDTA, embedded in paraffin, and sectioned in 3 planes. Sections (7 μm) were stained with toluidine blue O (pH, 8.5), Alcian blue (pH, 1.0), and resorcin-fuchsin-thiazin-picric acid, and by the method of Gomori according to the instructions of Romeis.5 Immunohistochemical investigations of extracellular matrix components were performed on cryosections of unfixed material (from 4 men and 4 women; age range, 47-78 years) that were frozen in liquid nitrogen. Polyclonal antibodies to collagen type I, type II (Biodesign, Kennebunk, Me), type III (Bio-Science Products AG, Emmenbrucke, Switzerland), and type IX were used. For scanning electron microscopy, 18 CAJs (from 12 men and 6 women; age range, 34-98 years) were separated into 36 articular facets. Six facets (3 cricoid and 3 arytenoid) were cut into 2 parts mediasagittally. Afterward, all facets and facet halves were fixed in 2.5% glutaraldehyde for 1 week. Six facets (3 cricoid and 3 arytenoid) were investigated without preceding maceration. The method of Ohtani et al6 was used for detailed representations of collagen fibrils in the articular cartilage of 7 CAJs. Eight CAJs were macerated in 10% hypochloric acid at 67°C for 15 to 30 minutes and then briefly rinsed in distilled water.

All tissue blocks were impregnated in 2.5% tannic acid for 2 days. A counterfixation in 2% osmium tetroxide for 4 hours was followed by dehydration in ethanol and drying in a critical point dryer. Articular facets were coated with gold and analyzed with a scanning electron microscope (Philips GmbH, Kassel, Germany).

SCANNING ELECTRON MICROSCOPY

Scanning electron microscopy revealed alterations of the articulating arytenoid and cricoid facets at varying levels of intensity (Figure 2). The earliest stage in the development of the lesion is characterized by a roughening of the articular surface, showing a cobblestone appearance (Figure 3). After maceration of the cartilage surface in roughened areas, large chondrocyte cavities were visible next to the joint surface (Figure 4). Advanced articular cartilage degeneration appeared as fibrillation of the superficial layer and led to exposure of collagenous fibers in a delimited area (Figure 5).

In most cases, only 1 degeneration focus is found per articular facet (Figure 2). Such a focus may affect most of the articular facet. In 3 joints, more than 1 degenerative focus was observed per facet. Degenerative changes occur more frequently and with higher intensity in the cricoid articular cartilage than in the arytenoid cartilage.

IMMUNOHISTOCHEMISTRY

Our investigation with antibodies to both type I and type III collagen indicated a high immunoreactivity in some areas of the superficial cartilage layers (Figure 6). These areas correspond to the areas of chondrocyte cluster formation seen in light microscopy and the areas of surface roughening seen in scanning electron microscopy. Deeper cartilage layers do not react to these antibodies (Figure 6). The deeper zones show an intensive response to antibodies to type II and type IX collagen, whereas the superficial layers reveal only weak or no reactivity to these antibodies in the areas of articular surface degeneration.

COMMENT

Aging of the voice is a complex process that has been poorly understood to date. A wealth of investigations have been carried out to study changes in the voice and laryngeal morphologic features with advancing age.

In this context, discussions on the structural changes of CAJs have been controversial. Segre4 describes the ero-
Kahane and coworkers\textsuperscript{7,8} find an unevenness of the cricoarytenoid articular surface with erosion, nicking, and fissurelike defects in some investigated joints. Using the india ink pinprick technique, they demonstrated that the changes are accompanied by a loss of viscoelasticity and fraying of collagenous fibers. They hypothesize that the alterations might influence the smoothness of the joint surface and, consequently, joint movement. This leads ultimately to glottal incompetence and concomitant senescent changes in the voice. By contrast, Casiano et al\textsuperscript{9} do not find articular surface irregularities in CAJs. They speculate that the fixation method used by Kahn and Kahane\textsuperscript{7} could have created artifacts in the older tissue and doubt the occurrence of detrimental alterations in CAJs of older patients.

The results of the present study show chondrocyte proliferation and changed collagen synthesis next to the

joint surface as well as fibrillation of the joint surface in CAJs of elderly individuals (Table) and thus verify the observations made by Segre, Kahn and Kahane, and Kahane and Hammons.

In joints of the limbs, senile changes appear predominantly in deeper cartilage zones, whereas osteoarthritids first occurs in the superficial layer of articular cartilage. In osteoarthritis, chondrocytes undergo metabolic changes because of a lack of balance between the quantity of joint load and the load capacity of the supporting tissue involved in joint structure composition.

In the early stages of the disease, there is a notable reduction of type IX collagen production. This leads to diminished cross-linking among type II collagen fibrils. The changes are distinguished by a roughening and degeneration of the articular surface, which is characterized by fibrillation of superficial cartilage.

As a result of damage in later stages of osteoarthritis, the integrity of the collagenous network is violated and its strength is lost. Cartilage becomes susceptible to mechanical rupture, the matrix splits, degeneration occurs, and vertical fissures arise in the cartilage surface. Large amounts of proteoglycans are washed out through the destroyed net tissue involved in joint structure composition.

Degenerative changes in the cartilage occur simultaneously with attempts to repair the matrix. Cell clusters adjacent to the joint surface are characteristic of mechanically caused arthritis. The Alcian blue technique reveals staining only around the clusters. Different collagen types, for example, types I, III, and X, also appear in the disrupted areas, which does not usually occur in adult joint cartilage.

The degenerative alterations in CAJs of elderly individuals presented herein can be compared with morphologic osteoarthritic changes in limb joints. Osteoarthritids in CAJs is demonstrable in persons aged 40 years or older. In elderly patients, the incidence is approximately 50%; thus, osteoarthritis is not a rare event (Table). This high incidence may be due to joint biomechanics, whereas further discussion is necessary to determine whether a partial loss of articular surface contact between cricoid and arytenoid cartilage occurs during adduction of the arytenoid cartilage. A comparable pathogenesis has been hypothesized for the carpometacarpal joint of the thumb.

In conclusion, the described degenerative changes in human CAJs are comparable to osteoarthritids in limb joints and may impair gross positional and postural movements of the arytenoid cartilage. The structural changes may impact respiratory and protective functions of the larynx and thus may have negative functional consequences for vocal production. For example, impaired smoothness of arytenoid motion could reduce the extent and degree of vocal ligament approximation during phonation, leading to aperiodicity in the vocal signal and thereby diminishing vocal quality. Such a voice is also likely to be reduced in intensity because of air leakage through incompletely or loosely approximated vocal ligaments.

Accepted for publication April 24, 1998.

We gratefully acknowledge gifts of polyclonal antibodies to type IX and type I collagen from the Department of Medical Molecular Biology, University of Lübeck, Lübeck, Germany.

Presented as a poster at the 68th annual meeting of the German Otorhinolaryngology Society, Head and Neck Surgery, Nürnberg, Germany, May 11, 1997, where it received first prize.

We would like to thank K. Stengel and R. Worm for their helpful expert technical assistance as well as H. Waluk and H. Siebke for their photographic work. We also thank M. Kimpel, MD, for his critical suggestions and W. U. Kampen, Dipl-Biol, MD, for his thorough proofreading of the draft translation.
